Abstract

We report the results of a search for flavor-changing neutral current, lepton-flavor violating, and lepton-number violating decays of D^+ , D_s^+ , and D^0 mesons (and their antiparticles) into modes containing muons and electrons. Using data from Fermilab charm hadroproduction experiment E791, we examine the $\pi\ell\ell$ and $K\ell\ell$ decay modes of D^+ and D_s^+ and the $\ell^+\ell^-$ decay modes of D^0 . No evidence for any of these decays is found. Therefore, we present branching-fraction upper limits at 90% confidence level for the 24 decay modes examined. Eight of these modes have no previously reported limits, and fourteen are reported with significant improvements over previously published results. © 1999 Published by Elsevier Science B.V. The $SU(2) \times U(1)$ Standard Model of electroweak interactions qualitatively accounts for the known decays of heavy quarks and can often quantitatively predict the decay rates. However, this model is incomplete in that it does not account for the number of quark and lepton families observed, nor the hierarchy of mass scales. Also unknown is the mechanism responsible for breaking the underlying gauge symmetry. One way to search for physics beyond the Standard Model is to search for decays that are forbidden or else are predicted to occur at a negligible level. Observing such decays would constitute evidence for new physics, and measuring their branching fractions would provide insight into how to modify our theoretical understanding, e.g., by introducing new particles or new gauge couplings.

In this letter we present the results of a search for 24 decay modes of the neutral and charged D mesons (which contain the heavy charm quark). These decay modes¹ fall into three categories:

(1) FCNC – flavor-changing neutral current decays ($D^0 \rightarrow \ell^+\ell^-$ and $D_{(d,s)}^+ \rightarrow h^+\ell^+\ell^-$, in which h is π or K);

(2) LFV – lepton-flavor violating decays ($D^0 \rightarrow \mu^\pm e^\mp$, $D_{(d,s)}^+ \rightarrow h^+\mu^\pm e^\mp$, and $D_{(d,s)}^+ \rightarrow h^-\mu^+e^+$, in which the leptons belong to different generations);

(3) LNV – lepton-number violating decays ($D_{(d,s)}^+ \rightarrow h^-\ell^+\ell^+$, in which the leptons belong to the same generation but have the same sign charge).

Decay modes belonging to (1) occur within the Standard Model via higher-order diagrams, but the estimated branching fractions are 10^{-8} to 10^{-6} [1]. Such small rates are below the sensitivity of current experiments. However, if additional particles such as supersymmetric squarks or charginos exist, they could contribute additional amplitudes that would make these modes observable. Decay modes belonging to (2) and (3) do not conserve lepton number and thus are forbidden within the Standard Model. However, lepton number conservation is not required by Lorentz invariance or gauge invariance, and a number of theoretical extensions to the Standard Model predict lepton-number violation [2]. Many experiments have searched for lepton-number violation in K decays, and for lepton-number violation and flavor-changing neutral currents in D and B decays. The limits we present here for rare and forbidden dilepton decays of the D mesons are typically more stringent than those obtained from previous searches [3], or else are the first reported.

¹ Charge-conjugate modes are included implicitly throughout this paper.

The data are from Fermilab experiment E791 [4], which recorded 2×10^{10} events with a loose transverse energy trigger. These events were produced by a 500 GeV/c π^- beam interacting in a target consisting of five thin foils that had 15 mm center-to-center separation along the beamline. The most upstream foil was 0.5 mm thick platinum. It was followed by four foils consisting of 1.6 mm thick diamond. Momentum analysis was provided by two dipole magnets that bent particles in the horizontal (x - z) plane. Position information for track and vertex reconstruction was provided by 23 silicon microstrip detectors (6 upstream and 17 downstream of the target) along with 10 planes of proportional wire chambers (8 upstream and 2 downstream of the target), and 35 drift chamber planes. The experiment also included electromagnetic and hadronic calorimeters, a muon detector, and two multi-cell Čerenkov counters that provided π/K separation in the momentum range 6–60 GeV/c [5]. The kaon identification criteria varied by search decay mode. We typically required that the momentum-dependent light yield in the Čerenkov counters be consistent with that of a kaon track measured in the spectrometer.

Electrons were identified by an electromagnetic calorimeter [6] that consisted of lead sheets and liquid scintillator located 19 m downstream of the target. Electron identification was based on energy deposition and transverse shower shape in the calorimeter. The electron identification efficiency varied from 62% for momenta below 9 GeV/c to 45% for momenta above 20 GeV/c. The decrease in efficiency with increasing momentum reflects the fact that higher momentum electrons populate a more congested region of the spectrometer. The pion misidentification rate was approximately 0.8%, independent of pion momentum.

Muon identification was obtained from two planes of scintillation counters. The plane that measured vertical coordinates (y) consisted of 16 scintillation counters, each 3 meters long and 14 cm wide. The plane that measured horizontal coordinates (x) consisted of 14 counters, each 3 meters long and covering a full width of 5.5 meters in the x -direction. The counters were located behind shielding with a thickness equivalent to 2.5 meters (15 interaction lengths) of iron. Candidate muon tracks projected into the muon system were required to pass a series of muon

quality criteria that were optimized with $D^+ \rightarrow \bar{K}^{*0} \mu^+ \nu_\mu$ decays from our data [7]. Timing information from the y -coordinate counters was used to improve the position resolution in the x -direction. The efficiencies of the muon counters were measured in special runs using muons originating from the primary beam dump, and were found to be $(99 \pm 1)\%$ for the y -coordinate counters and $(69 \pm 3)\%$ for the x -coordinate counters. The probability for misidentifying a pion as a muon decreased as momentum increased, from about 6% at 8 GeV/c to $(1.3 \pm 0.1)\%$ for momenta greater than 20 GeV/c.

After reconstruction, events with evidence of well-separated production (primary) and decay (secondary) vertices were retained for further analysis. To separate charm candidates from background, we required the following: that secondary vertices be well-separated from the primary vertex and located well outside the target foils and other solid material; that the momentum vector of the candidate charm meson point back to the primary vertex; and that the decay track candidates pass approximately 10 times closer to the secondary vertex than to the primary vertex. A secondary vertex had to be separated from the primary vertex by greater than $20 \sigma_L$ for D^+ decays and greater than $12 \sigma_L$ for D^0 and D_s^+ decays, where σ_L is the calculated resolution of the measured longitudinal separation. In addition, the secondary vertex had to be separated from the closest material in the target foils by greater than $5 \sigma'_L$, where σ'_L is the uncertainty in this separation. The sum of the vector momenta of the tracks from the secondary vertex was required to pass within $40 \mu\text{m}$ of the primary vertex in the plane perpendicular to the beam. Finally, the net momentum of the charm candidate transverse to the line connecting the production and decay vertices had to be less than 300 MeV/c for D^0 candidates, less than 250 MeV/c for D_s^+ candidates, and less than 200 MeV/c for D^+ candidates. These selection criteria and, where possible, the kaon identification requirements, were the same for the search mode and for its normalization signal.

For this study we used a “blind” analysis technique. Before our selection criteria were finalized, all events having masses within a mass window ΔM_S around the mass of D^+ , D_s^+ , or D^0 were “masked” so that the presence or absence of any potential

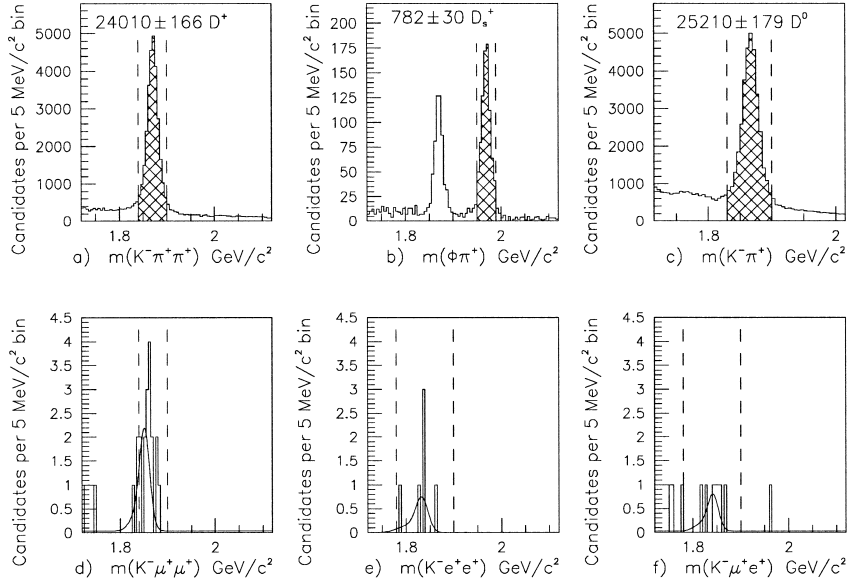

Fig. 1. Top row: typical charm signals in normalization modes used for the a) D^+ , b) D_s^+ , and c) D^0 decay modes. The signal region is shaded. Bottom row: invariant mass plots of D^+ candidate decays to d) $K^-\mu^+\mu^+$, e) $K^-e^+e^+$, and f) $K^-\mu^+e^+$, showing reflections primarily from misidentified $D^+ \rightarrow K^-\pi^+\pi^+$ decays. These modes are not used to set upper limits but are instead used to estimate misidentification rates following the method described in the text. The solid curves are normalized Monte Carlo fits. The dashed lines show the signal window.

signal candidates would not bias our choice of selection criteria. All criteria were then chosen by studying signal events generated by a Monte Carlo simulation program (see below) and background events from real data. Events within the signal windows were unmasked only after this optimization. Background events were chosen from a mass window ΔM_B above and below the signal window ΔM_S . The criteria were chosen to maximize the ratio $N_S/\sqrt{N_B}$, where N_S and N_B are the numbers of signal and background events, respectively. We used asymmetric windows for the decay modes containing electrons to allow for the bremsstrahlung low-energy tail. The signal windows are:

$$\begin{aligned}
 &1.84 < M(D^+) < 1.90 \text{ GeV}/c^2 \text{ for } D^+ \rightarrow h\mu\mu, \\
 &1.78 < M(D^+) < 1.90 \text{ GeV}/c^2 \text{ for } D^+ \rightarrow hee \text{ and } h\mu e, \\
 &1.95 < M(D_s^+) < 1.99 \text{ GeV}/c^2 \text{ for } D_s^+ \rightarrow h\mu\mu, \\
 &1.91 < M(D_s^+) < 1.99 \text{ GeV}/c^2 \text{ for } D_s^+ \rightarrow hee \text{ and } h\mu e, \\
 &1.83 < M(D^0) < 1.90 \text{ GeV}/c^2 \text{ for } D^0 \rightarrow \mu\mu, \\
 &1.76 < M(D^0) < 1.90 \text{ GeV}/c^2 \text{ for } D^0 \rightarrow ee \text{ and } \mu e.
 \end{aligned} \tag{1}$$

We normalize the sensitivity of our search to topologically similar Cabibbo-favored decays. For the D^+ decays we use $D^+ \rightarrow K^-\pi^+\pi^+$; for D_s^+ decays we use $D_s^+ \rightarrow \phi\pi^+$; and for D^0 decays we use $D^0 \rightarrow K^-\pi^+$. The widths of our normalization modes were $10.5 \text{ MeV}/c^2$ for D^+ , $9.5 \text{ MeV}/c^2$ for D_s^+ , and $12 \text{ MeV}/c^2$ for D^0 . The events within the $\sim 5\sigma$ window are shown in Fig. 1a–c. The upper limit for each branching fraction B_X is calculated using the following formula:

$$B_X = \frac{N_X}{N_{\text{Norm}}} \frac{\varepsilon_{\text{Norm}}}{\varepsilon_X} B_{\text{Norm}} \tag{2}$$

where N_X is the 90% CL upper limit on the number of decays for the rare or forbidden decay mode X , and ε_X is that mode's detection efficiency. N_{Norm} is the fitted number of normalization mode decays; $\varepsilon_{\text{Norm}}$ is the normalization mode detection efficiency; and B_{Norm} is the normalization mode branching fraction obtained from the Particle Data Group [3].

The ratio of detection efficiencies is

$$\frac{\varepsilon_{\text{Norm}}}{\varepsilon_X} = \frac{N_{\text{Norm}}^{\text{MC}}}{N_X^{\text{MC}}} \quad (3)$$

where $N_{\text{Norm}}^{\text{MC}}$ and N_X^{MC} are the fractions of Monte Carlo events that are reconstructed and pass the final selection criteria, for the normalization and decay modes respectively. The simulations use PYTHIA/JETSET [8] as the physics generator and model the effects of resolution, geometry, magnetic fields, multiple scattering, interactions in the detector material, detector efficiencies, and the analysis selection criteria. The efficiencies for the normalization modes varied from approximately 0.5% to 2% depending on the mode, and the efficiencies for the search modes varied from approximately 0.1% to 2%.

Monte Carlo studies show that the experiment's acceptances are nearly uniform across the Dalitz

plots, except that the dilepton identification efficiencies typically drop to near zero at the dilepton mass threshold. While the loss in efficiency varies channel by channel, the efficiency typically reaches its full value at masses only a few hundred MeV/ c^2 above the dilepton mass threshold. We use a constant weak-decay matrix element when calculating the overall detection efficiencies. Two exceptions to the use of the Monte Carlo simulations in determining relative efficiencies are made: those for Čerenkov identification when the number of kaons in the signal and normalization modes are different, and those for the muon identification. These efficiencies are determined from data.

The 90% CL upper limits N_X are calculated using the method of Feldman and Cousins [9] to account for background, and then corrected for systematic errors by the method of Cousins and Highland [10].

Table 1

E791 90% confidence level (CL) branching fractions (BF) compared to PDG98 limits. The background and candidate events correspond to the signal region only.

Mode	Est. BG		Cand. Obs.	Syst. Err.	90% CL Num.	E791 BF Limit	PDG98 [3] BF Limit

$D_s^+ \rightarrow K^+ \mu^\pm e^\mp$	0.40	0.70	1	27%	3.57	6.3×10^{-4}	
$D_s^+ \rightarrow K^- \mu^+ \mu^+$	0.40	0.64	0	26%	1.68	1.8×10^{-4}	5.9×10^{-4}
$D_s^+ \rightarrow K^- e^+ e^+$	0.00	0.39	0	28%	2.22	6.3×10^{-4}	
$D_s^+ \rightarrow K^- \mu^+ e^+$	0.80	0.35	1	27%	3.53	6.8×10^{-4}	
$D_s^+ \rightarrow \pi^+ \mu^+ \mu^-$	0.93	0.72	1	27%	3.02	1.4×10^{-4}	4.3×10^{-4}
$D_s^+ \rightarrow \pi^+ e^+ e^-$	0.00	0.83	0	29%	1.85	2.7×10^{-4}	
$D_s^+ \rightarrow \pi^+ \mu^\pm e^\mp$	0.00	0.72	2	30%	6.01	6.1×10^{-4}	
$D_s^+ \rightarrow \pi^- \mu^+ \mu^+$	0.80	0.36	0	27%	1.60	8.2×10^{-5}	4.3×10^{-4}
$D_s^+ \rightarrow \pi^- e^+ e^+$	0.00	0.42	1	29%	4.44	6.9×10^{-4}	
$D_s^+ \rightarrow \pi^- \mu^+ e^+$	0.00	0.36	3	28%	8.21	7.3×10^{-4}	
$D^0 \rightarrow \mu^+ \mu^-$	1.83	0.63	2	6%	3.51	5.2×10^{-6}	4.1×10^{-6}
$D^0 \rightarrow e^+ e^-$	1.75	0.29	0	9%	1.26	6.2×10^{-6}	1.3×10^{-5}
$D^0 \rightarrow \mu^\pm e^\mp$	2.63	0.25	2	7%	3.09	8.1×10^{-6}	1.9×10^{-5}

In these methods, the numbers of signal events are determined by simple counting, not by a fit. All results are listed in Table 1 and shown in Figs. 2 and

3. The kinematic criteria and removal of reflections (see below) are different for the D^+ , D_s^+ , and D^0 . Thus, the D^+ and D_s^+ rows in Fig. 2 with the same

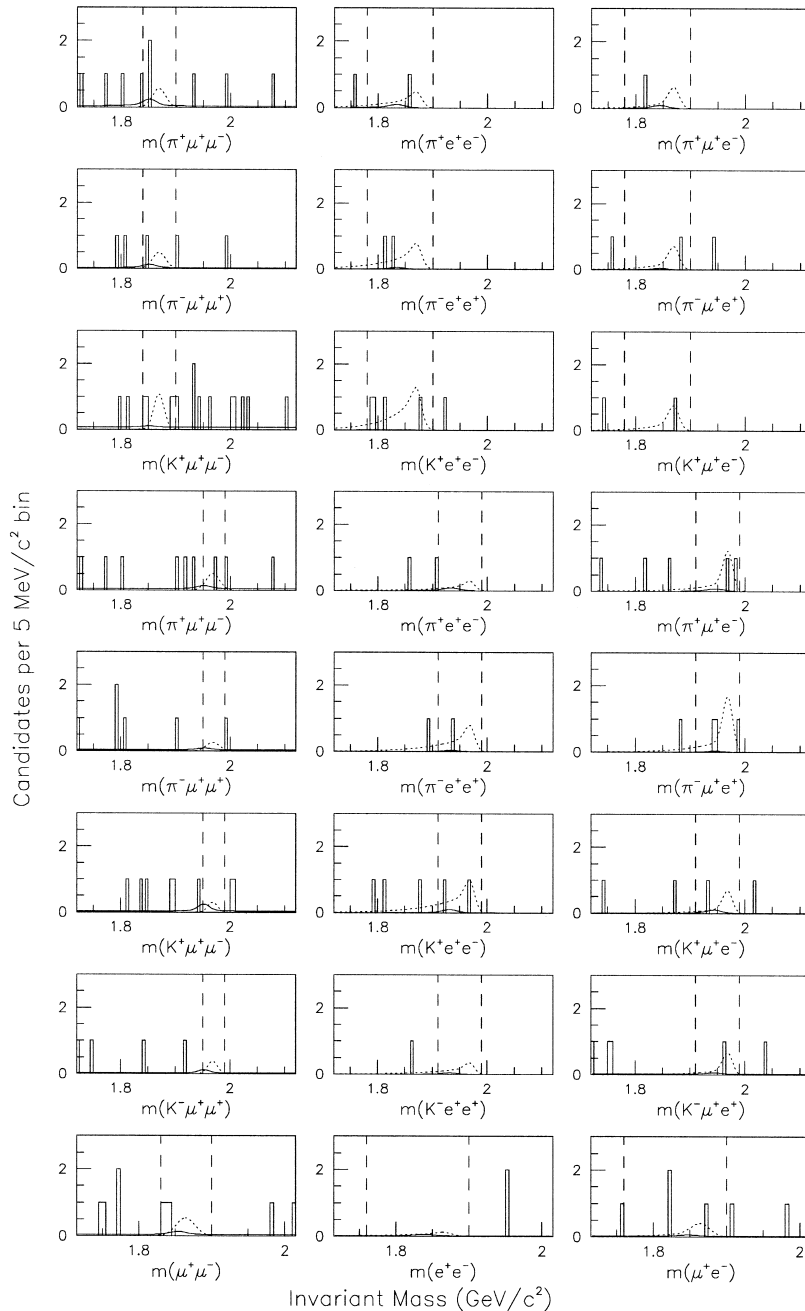

Fig. 2. Final event samples for the D^+ (rows 1–3), D_s^+ (rows 4–7), and D^0 (row 8) decays. The solid curves represent estimated background; the dotted curves represent signal shape for a number of events equal to the 90% CL upper limit. The dashed vertical lines are ΔM_S boundaries.

Fig. 3. Comparison of the 90% CL upper-limit branching fractions from E791 data (dark circles) with existing limits (open diamonds) from the 1998 PDG [3].

decay particles are different, and the seventh row of Fig. 2 is different from the bottom row of Fig. 1.

The upper limits are determined by both the number of candidate events and the expected number of background events within the signal region. Background sources that are not removed by the selection criteria discussed earlier include decays in which hadrons (from real, fully-hadronic decay vertices) are misidentified as leptons. In the case where kaons are misidentified as leptons, candidates have effective masses which lie outside the signal windows. Most of these originate from Cabibbo-favored modes $D^+ \rightarrow K^- \pi^+ \pi^+$, $D_s^+ \rightarrow K^- K^+ \pi^+$, and $D^0 \rightarrow K^- \pi^+$ (and charge conjugates). These Cabibbo-favored reflections are explicitly removed prior to the selection-criteria optimization. There remain two sources of background in our data: hadronic decays with pions misidentified as leptons (N_{MisID}) and ‘‘combi-

natoric’’ background (N_{Cmb}) arising primarily from false vertices and partially reconstructed charm decays. After selection criteria were applied and the signal windows opened, the number of events within the window is $N_{\text{Obs}} = N_{\text{Sig}} + N_{\text{MisID}} + N_{\text{Cmb}}$.

The background N_{MisID} arises mainly from singly-Cabibbo-suppressed (SCS) modes. These misidentified leptons can come from hadronic showers reaching the muon counter, decays-in-flight, and random overlaps of tracks from otherwise separate decays (‘‘accidental’’ sources). We do not attempt to establish a limit for $D^+ \rightarrow K^- \ell^+ \ell^+$ modes, as they have relatively large feedthrough signals from copious Cabibbo-favored $K^- \pi^+ \pi^+$ decays. Instead, we use the observed signals in $K^- \ell^+ \ell^+$ channels to measure three dilepton misidentification rates under the assumption that the observed signals (shown in Fig. 1d–f) arise entirely from lepton misidentifica-

tion. The curve shapes were determined from Monte Carlo simulations. The following misidentification rates were obtained: $r_{\mu\mu} = (7.3 \pm 2.0) \times 10^{-4}$, $r_{\mu e} = (2.9 \pm 1.3) \times 10^{-4}$, and $r_{ee} = (3.4 \pm 1.4) \times 10^{-4}$. Using these rates we estimate the numbers of misidentified candidates, $N_{\text{MisID}}^{h\ell\ell}$ (for D^+ and D_s^+) and $N_{\text{MisID}}^{\ell\ell}$ (for D^0), in the signal windows as follows:

$$N_{\text{MisID}}^{h\ell\ell} = r_{\ell\ell} N_{\text{SCS}}^{h\pi\pi} \quad \text{and} \quad N_{\text{MisID}}^{\ell\ell} = r_{\ell\ell} N_{\text{SCS}}^{\pi\pi}, \quad (4)$$

where $N_{\text{SCS}}^{h\pi\pi}$ and $N_{\text{SCS}}^{\pi\pi}$ are the numbers of SCS hadronic decay candidates within the signal windows. For modes in which two possible pion combinations can contribute, e.g., $D^+ \rightarrow h^+ \mu^\pm \mu^\mp$, we use twice the above rate. These misidentification backgrounds were typically small or negligible.

To estimate the combinatoric background N_{Cmb} within a signal window ΔM_S , we count events having masses within an adjacent background mass window ΔM_B , and scale this number ($N_{\Delta M_B}$) by the relative sizes of these windows:

$$N_{\text{Cmb}} = \frac{\Delta M_S}{\Delta M_B} N_{\Delta M_B}. \quad (5)$$

To be conservative in calculating our 90% confidence level upper limits, we take combinatoric backgrounds to be zero when no events are located above the mass windows. In Table 1 we present the numbers of combinatoric background, misidentification background, and observed events for all 24 modes.

The sources of systematic errors in this analysis include: statistical errors from the fit to the normalization sample N_{Norm} ; statistical errors on the numbers of Monte Carlo generated events for both $N_{\text{Norm}}^{\text{MC}}$ and N_X^{MC} ; uncertainties in the calculation of misidentification background; and uncertainties in the relative efficiency for each mode, including lepton and kaon tagging efficiencies. These tagging efficiency uncertainties include: 1) the muon counter efficiencies from both Monte Carlo simulation and hardware performance; 2) kaon Čerenkov identification efficiency due to differences in kinematics and modeling between data and Monte Carlo simulated events; and 3) the fraction of signal events (based on simulations) that would remain outside the signal

window due to bremsstrahlung tails. The larger systematic errors for the D_s^+ modes, compared to the D^+ and D^0 modes, are due to the uncertainty in the branching fraction for the D_s^+ normalization mode. The sums, taken in quadrature, of these systematic errors are listed in Table 1.

In summary, we use a ‘‘blind’’ analysis of data from Fermilab experiment E791 to obtain upper limits on the dilepton branching fractions for flavor-changing neutral current, lepton-number violating, and lepton-family violating decays of D^+ , D_s^+ , and D^0 mesons. No evidence for any of these decays is found. Therefore, we present upper limits on the branching fractions at the 90% confidence level. These limits represent significant improvements over previously published results. Eight new D_s^+ search modes are reported. A comparison of our 90% C.L. upper limits with previously published results [3] is shown in Fig. 3.
